## Description

## A Method of Forming a Silicon Dioxide Layer

- 5 The present invention refers to a method of forming a silicon dioxide layer by thermally oxidizing at least one silicon surface region on a semiconductor substrate, said silicon surface region having a curved surface.
- 10 A silicon dioxide layer which is commonly used as an isolating or passivating layer can be generated on a silicon surface for example by thermal oxidation. Thermal oxides are grown when a silicon layer is held at a temperature between 700°C and 1200°C in an oxidizing atmosphere. In particular,
- 15 thick field oxide layers which are used for integrated MOS circuits can be produced by the LOCOS (Local Oxidation of Silicon) process wherein the portions on which the silicon dioxide layer is not to be grown are covered by a masking layer such as made of silicon nitride.
- 20 The growth rate of thermal oxides usually depends on one side on the crystal orientation of the underlying silicon layer. On the other side, if thermal oxides are to be grown on curved surfaces, the growth rate also depends on the direction and the amount of the curvature. Since during thermal
- 25 oxidation the volume of the former silicon layer increases due to the interstitially embedded oxygen atoms, stress which is dependent on the specific curvature is induced which in turn will result in an inhomogenous growth of the silicon dioxide layer thickness.
- 30 As a consequence, only inhomogenous layer thicknesses are achieved on curved silicon surfaces.
- 35 In the past, this problem has been dealt with by thermally oxidizing only non-curved or equally curved silicon surfaces. Alternatively, the thickness of the grown silicon dioxide

layer has been chosen so that even the thinnest area has the desired thickness. In addition, in the manufacture of devices demanding for homogenous oxide layer thicknesses, the silicon dioxide layer has been produced on curved silicon surfaces by  
5 a deposition method in which the growth rate does not depend on the curvature.

One example wherein it would be highly desirable to thermally grow a homogenous silicon dioxide layer on a curved silicon  
10 surface refers to the formation of the collar region in the upper part of the trench of a DRAM (Dynamic Random Access Memory) cell.

Such a memory cell comprises an access transistor as well as  
15 a storage capacitor for storing a charge representing a data in the form of either a logical "1" or a logical "0". When the data is read from the memory cell, sense amplifiers detect the level of the charge stored on a particular capacitor so as to produce a logical "1" or a logical "0" output based  
20 on the stored charge.

The capacitor can for example be formed in a trench in the semiconductor substrate. The trench is filled with a dielectric and with polysilicon acting as the top electrode of the  
25 capacitor. In order to suppress the formation of a parasitic transistor in the upper part of the capacitor trench, it is necessary to provide an isolation collar, for example of silicon dioxide in the upper trench portion. This isolation collar has a length of approximately 1  $\mu\text{m}$  and a thickness  
30 sufficient, that is approximately 25 nm, so as to suppress the transistor action. Since the trench usually assumes an oval cross section, the silicon surface is curved, which makes a uniform thermal oxide growth according to conventional methods impossible.

35

It is therefore an object of the present invention to provide a method of forming a thermally grown silicon dioxide layer

on curved surfaces by which a homogenous layer thickness can be achieved.

According to the present invention, the above object is

5 achieved by a method of forming a silicon dioxide layer comprising the steps of

- providing a semiconductor substrate having at least one silicon surface region having a curved surface,
- roughening the surface of said at least one silicon surface
- 10 region so as to produce a layer of porous silicon, and
- thermally oxidizing said at least one roughened curved silicon surface region.

Moreover, the present invention provides a method of produc-  
15 ing an isolation collar of a storage trench capacitor forming part of a memory cell comprising the steps of

- providing a semiconductor substrate having a trench with a curved inner surface of silicon, said trench extending vertically with respect to the substrate surface,
- 20 - covering the surface regions which are not to be oxidized with a silicon nitride layer,
- roughening the surface of said curved silicon surface region so as to produce a layer of porous silicon, and
- thermally oxidizing said roughened curved silicon surface
- 25 region.

As the inventors of the present invention found out, silicon dioxide can be homogeneously grown on curved silicon surfaces if the silicon surface is roughened before the thermal oxidation process. In particular, a roughening process producing  
30 pores having a structural size of less than 20 nm has achieved excellent results.

This can be explained on the basis of two different theories.

35 On one side, as has been mentioned above, the growth rate depends on the crystal orientation of the underlying silicon

layer. By roughening the silicon layer, on an average the crystal orientations are made isotropical and, as a consequence, a homogenous growth rate is achieved.

5 Alternatively, it can be thought that the stress inside the silicon and silicon dioxide layers depends on the curvature. When silicon dioxide is thermally grown, oxygen atoms from the surrounding atmosphere have to diffuse across the superficial silicon dioxide layer. The diffusion constant depends  
10 on the stress inside the silicon dioxide layer. By roughening the curved silicon surface, silicon atoms are removed and pores are created. These pores reduce or make uniform the stress prevailing inside the silicon layer and, thus, make uniform the silicon dioxide growth rate. As a consequence,  
15 silicon dioxide can thermally be grown with a homogenous growth rate even on curved surfaces.

The invention is applicable to surfaces of monocrystalline silicon and to surfaces of polycrystalline silicon as well.

20

According to the present invention, it is preferred that the size of the pores produced by the roughening step does not exceed 20 nm, more preferably 10 nm. If the size of the pores is too large, the thermal oxide layer will become too unstable. On the other hand, if the size of the pores becomes too  
25 small, in particular, substantially lower than 1 nm, the effect of the present invention will become too weak and the roughening will be insufficient. It is assumed that at a porosity of 50 % even a pore size of 1 nm and slightly smaller  
30 will provide satisfactory results.

According to the present invention, the creation of micropores having a defined size of less than 5 nm is especially preferred since it has been observed that in this case additionally the dielectric constant of the grown silicon dioxide  
35 layer is lowered. Moreover, if a microporous silicon surface

region is produced, the effect of the crystal direction on the growth rate additionally becomes negligible.

In particular, the required homogeneity can be achieved if the partition walls between neighbouring pore structures can homogeneously be oxidized. Since in the case of a microporous silicon surface region the partition walls only have a thickness of 2 to 5 nm, this can easily be accomplished.

The roughening step can be accomplished by electrochemically or by electroless etching.

For example, generally known liquid mixtures can be used for electrochemically etching such as a bath of a 6% aqueous solution of hydrofluoric acid, or a mixture of a 49% aqueous hydrofluoric acid and pure ethyl alcohol at a ratio of 0,75 : 0,25. In this case, an anodic etching process as generally known in the art is performed.

Alternatively, it is preferred to electroless etch the silicon surface, for example in a solution containing phosphoric acid, or a so-called stain-etch solution, for example having a composition of  $\text{H}_2\text{SO}_4:\text{HF}:\text{HNO}_3 = 7:1:0.01$ .

The use of an electroless etching process is particularly advantageous since in this case no electrical contact has to be made between the silicon surface region and a cathode placed in the etching solution. This greatly simplifies the roughening step.

After the roughening step, a thermal oxidation step for thermally oxidizing the at least one roughened monocrystalline or polycrystalline silicon surface is performed in accordance with commonly used methods. In particular, the substrate is held at a temperature between 700°C and 1200°C in an oxidizing atmosphere, for example pure oxygen or water. According to the present invention, it is preferred that the oxidation

step is performed so that not only the roughened portion is oxidized but that the oxidized portion extends to a depth which is slightly greater than the formerly roughened depth. As a consequence, sharp boundaries between silicon and silicon dioxide are created. The oxidation time depends on the size of the pores as well as on the thickness of the partition walls between neighbouring pores.

The method of the present invention can advantageously be applied for locally oxidizing a curved silicon surface according to the LOCOS process as mentioned above. In this case, the portions on which no silicon dioxide layer is to be formed are covered by a masking material such as silicon nitride. The portions on which the silicon dioxide layer is to be formed remain exposed so as to enable the reaction between the silicon and the oxygen in the oxidizing atmosphere. When covering the selected portions with a masking layer, special care has to be taken so as to ensure that the masking material will not be affected by the etching solution for roughening the surface. In particular, if silicon nitride is used as the masking material, the etching solution must not contain phosphoric acid.

In summary, the present invention provides the following advantages:

- By the present invention, it becomes possible to thermally oxidize curved silicon surfaces so that a homogenous oxide thickness is achieved. Accordingly, thermal oxidation and, in particular, the LOCOS process can be applied for oxidizing curved surfaces even if a homogenous layer thickness is necessary.

- As a consequence, the advantages of the thermal oxidation process with respect to a deposition process can be exploited. In particular, thermal oxidation processes are cheaper and easier to perform. Moreover, since no deposition takes

place the diameter of trenches to be provided with a  $\text{SiO}_2$  liner for example will not substantially be reduced.

- Moreover, if the silicon surface is made microporous in the roughening step, the growth rate of the silicon dioxide will not depend on the crystal orientation, and the resulting silicon dioxide layer will have a smaller dielectric constant than the conventional.

In the following, the present invention will be explained in detail with reference to the accompanying drawings. Although the formation of the collar region of a DRAM cell is described, it is clearly to be understood that the invention can as well be used for thermally growing oxides which are used in any field of application, for example including an isolator in wafer bonding or for forming contact holes.

Figures 1 to 5 illustrate the steps for forming a collar in a memory cell according to a first embodiment of the present invention;

Figure 6 schematically illustrates a cross sectional view of the completed memory cell according to the first and second embodiment of the present invention;

Figure 7 illustrates the layout of a memory cell array; and

Figures 8 to 11 illustrate the steps for forming a collar in a memory cell according to a second embodiment of the present invention.

In Figure 1, reference numeral 1 denotes a monocrystalline silicon substrate having a main surface 2. An  $\text{SiO}_2$  layer 3

having a thickness of 5 nm and an  $\text{Si}_3\text{N}_4$  4 layer having a thickness of 200 nm are coated onto the main surface 2. A boron silicate glass layer or a silicon oxide layer 41 having a thickness of 1000 nm is applied as a hard mask material.

5

Using a photolithographically generated mask (not shown), the boron silicate glass mask layer or silicon oxide mask layer 41, the  $\text{Si}_3\text{N}_4$  layer 4 and the  $\text{SiO}_2$  layer 3 are patterned by a plasma etching process using  $\text{CF}_4/\text{CH}_3\text{F}$  so as to form a hard mask. After removal of the photolithographically generated mask trenches 5 having a depth of approximately 150 nm are etched into the main surface 2 by a further plasma etching process with  $\text{HBr}/\text{NF}_3$  using the hard mask as an etching mask. The etching depth is controlled by setting an appropriate etching time.

15

The trenches have for example a width of 100 x 250 nm and a distance of 100 nm from each other.

20 In a next step, a silicon nitride layer 12 having a thickness of 20 nm for protecting the buried strap portion is deposited by a chemical vapour deposition process in the trenches. By anisotropically plasma etching using for example  $\text{CHF}_3$ , the bottom portion of the silicon nitride layer as well as the portion on top of the hard mask is removed.

25

In the following step, the trenches are further etched by a plasma etching process with  $\text{HBr}/\text{NF}_3$  using the hard mask as an etching mask so that an additional depth of 1  $\mu\text{m}$  corresponding to the length of the isolation collar portion is achieved.

30

Then, the process of the present invention for producing the isolation collar 9 will be performed. The isolation collar is provided for suppressing the parasitic transistor which otherwise would be formed in the upper trench region of a trench capacitor.

35

Accordingly, the step of roughening the surface of the exposed silicon portion is performed by etching in a stain etch, for example of  $\text{H}_2\text{SO}_4:\text{HF}:\text{HNO}_3 = 7:1:0.01$ , for a time sufficient so as to generate micropores extending in a depth of approximately 20 nm in the surface area.

Thereafter, a thermal oxidation step is performed. To this end, the wafer is placed in an oxidation furnace at  $1050^\circ\text{C}$  in an atmosphere of for example pure oxygen or water so as to form a silicon dioxide layer having a thickness of 25 nm. More specifically, the porous surface portion is completely oxidized and, in addition, further 5 nm of the non-porous monocrystalline silicon material beneath the porous surface portion are oxidized. The process parameters are chosen in accordance with those usually employed. Since the upper part of the trench is covered by the silicon nitride layer, the silicon oxide will only be produced in the bottom part of the trench. (see Figure 2)

According to the present invention, the trenches having an oval diameter are covered by a uniform silicon dioxide layer having a homogenous thickness which is due to the roughening step performed.

Thereafter, the  $\text{SiO}_2$  layer on the bottom portion of the trenches is removed by anisotropically etching using  $\text{C}_4\text{F}_8$  as an etching gas. Optionally, a silicon nitride liner is deposited for protecting the collar region during the following process steps.

Then, the trenches are further etched by plasma etching process with  $\text{HBr}/\text{NF}_3$  using the hard mask as an etching mask until the final depth of  $5\text{ }\mu\text{m}$  is achieved. (see Figure 3)

Thereafter, the commonly used process for forming a DRAM cell is performed.

To this end, first, the bottom electrode 6, the capacitor dielectric 7 and the top electrode 8 of the storage capacitor are formed. The bottom electrode 6 can for example be implemented as a highly doped region or as a metallic electrode as is generally known in the art. As the capacitor dielectric 7, a layer having a thickness of approximately 5 nm comprising  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  as well as optionally silicon oxynitride can be used. However, other known materials such as  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$  or  $\text{Ta}_2\text{O}_5$  or a mixture of these can as well be used. The upper electrode 8 can for example be formed by depositing a polysilicon layer 10 which is doped in situ having a thickness 200 nm. (see Figure 4)

Thereafter, the top electrode will be patterned in a suitable manner and it will be connected with the source/drain portions of an access transistor.

For example, this can be accomplished by etching the polysilicon trench fill 10 up to approximately 200 nm beneath the main surface 2. Then, the dielectric layer 7 is removed from the surface of the silicon nitride layer 12 protecting the trench wall, for example by a deglassing step which is performed by shortly dipping the substrate into a hydrofluoric acid thus removing silicon oxynitride. Then, the silicon nitride layer 12 is removed, for example, by etching in hot phosphoric acid. As a consequence, the upper portion of the trench wall is exposed for forming a buried strap. (see Figure 5)

After a sacrificial oxidation for forming a scattering oxide (not shown), an implantation step will be performed so as to create a  $n^+$ -doped region 14 in the side wall of each trench 5 in the main surface 2 portion.

As is shown in Figure 6, the space above the polysilicon fill 10 in each of the trenches 5 will be filled by deposit-

ing in situ doped polysilicon and etching back the polysilicon with  $\text{SF}_6$  so as to form a polysilicon fill 11. The polysilicon fill 11 acts as a buried strap connecting the top capacitor electrode 8 and the  $n^+$ -doped region 14.

5

In a following step, isolation portions 13 for providing shallow trench isolation surrounding and defining the active areas are formed. To this end, a mask which defines the active areas is formed. By non-selectively plasma etching of silicon, silicon dioxide and polysilicon using  $\text{CHF}_3/\text{N}_2/\text{NF}_3$  with an etching time which is adjusted so as to etch 200 nm polysilicon, by removing the photoresist mask used therefor with  $\text{O}_2/\text{N}_2$ , by wet chemical etching of 3 nm dielectric layer, by oxidation and depositing a  $\text{Si}_3\text{N}_4$  layer having a thickness of 5 nm and by depositing a  $\text{SiO}_2$  layer having a thickness of 250 nm by a TEOS process and subsequent chemical mechanical polishing, the isolation portions 8 are finished. The  $\text{Si}_3\text{N}_4$  layer 4 will be removed by etching in hot phosphoric acid and the  $\text{SiO}_2$  layer 3 will be removed by etching in diluted hydrofluoric acid.

20

Next, by performing a sacrificial oxidation a scattering oxide will be formed. Photolithographically generated masks and implantations will be used for forming n-doped wells, p-doped wells and for performing implantations for setting the threshold voltages in the peripheral portion and the access transistors of the cell array. Moreover, an implantation with high energetic ions will be performed for doping the substrate portion which is remote from the main surface 2. Thereafter, a  $n^+$ -doped region will be formed by a so-called buried-well implant for connecting neighbouring bottom electrodes 6 with each other.

30

In the following, the transistor will be completed by defining the gate oxide as well as the gate electrode 16, corresponding wirings and the source and drain electrode 15, respectively, using commonly used process steps.

35

Thereafter, the memory cell array will be finished by forming further metalization layers as is generally known in the art.

5 Figure 7 shows the layout of an exemplary memory cell array implementing a so-called  $8\text{-}F^2$ -cell architecture comprising a storage trench capacitor and a planar transistor for each of the memory cells. For each of the memory cells an area of  $8F^2$  is needed, wherein  $F$  denotes the smallest structural length  
10 which can be produced in the technology employed. The bitlines BL are implemented as stripes and are extending parallel to each other, wherein the width as well as the distance between each of the bitlines amount to  $F$ , respectively. The word lines WL each having a width as well as a distance to  
15 each other of  $F$ , respectively, are arranged perpendicularly to the bitlines BL.

The active areas A of each of the memory cells are arranged beneath the bit lines BL, and two wordlines WL are crossing  
20 each other above each of the active areas A. The active areas A are arranged at staggered positions to each other beneath neighbouring bit lines BL. The trenches 5 having an oval diameter are disposed beneath the word lines WL. A gate electrode 16 of the corresponding transistor is disposed at the  
25 crossing points between one of the bit lines BL and one of the wordlines WL within the active areas A.

The active areas A extend between two trenches 5. Each of the active areas A comprises two transistors, which are connected  
30 with the corresponding bitline BL via a common bitline contact BLK. In dependence from the actuated wordline WL, the corresponding storage capacitor which is disposed in one of the two trenches 5, is read out.

35 It is to be understood that the advantages of the invention are achieved with monocrystalline silicon surfaces as well as with polycrystalline silicon surfaces.

According to a second embodiment of the present invention, as is shown in Figure 8, the deep trenches 5 are completely etched before performing the process of the present invention. A monocrystalline silicon substrate having a main surface 2 is coated with an  $\text{SiO}_2$  layer 3 having a thickness of 5 nm and an  $\text{Si}_3\text{N}_4$  4 layer having a thickness of 200 nm. A boron silicate glass layer (not shown) having a thickness of 1000 nm is applied as a hard mask material.

Using a photolithographically generated mask (not shown), the boron silicate glass layer, the  $\text{Si}_3\text{N}_4$  layer 4 and the  $\text{SiO}_2$  layer 3 are patterned by a plasma etching process using  $\text{CF}_4/\text{CH}_3\text{F}$  so as to form a hard mask. After removal of the photolithographically generated mask the trenches 5 are etched into the main surface 2 by a further plasma etching process with  $\text{HBr}/\text{NF}_3$  using the hard mask as an etching mask.

The trenches 5, for example, have a depth of 5  $\mu\text{m}$ , a width of 100 x 250 nm and a distance from each other of 100 nm. (see Figure 8)

Then, the bottom electrode 6, the capacitor dielectric 7 and the top electrode 8 of the storage capacitor are formed. The bottom electrode 6 can for example be implemented as a highly doped region or as a metallic electrode as is generally known in the art. In dependence from the specific implementation of the bottom electrode 6, it can be necessary to provide a silicon nitride layer for protecting the collar portion of the trench. In particular, in case the bottom electrode 6 is implemented as a highly doped region which is generated by diffusion doping using a gaseous source such as  $\text{AsH}_3$ , for example, it will be necessary to provide a silicon nitride layer as is generally known in the art in the upper trench portion in order to prevent the collar region from being doped.

As the capacitor dielectric 7, a layer having a thickness of approximately 5 nm comprising  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  as well as optionally silicon oxynitride can be used. However, other known materials such as  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$  or  $\text{Ta}_2\text{O}_5$  or a mixture of these can as well be used. The upper electrode 8 can for example be formed by depositing a polysilicon layer 10 which is doped in situ having a thickness 200 nm (see Figure 9).

In the next step, the upper electrode material 10 is recessed for preparing the buried strap contact. To this end, approximately 150 nm of the polysilicon layer are etched with  $\text{SF}_6$ .

Then, the dielectric layer 7 is removed from the surface of the upper trench wall, for example by a deglassing step which is performed by shortly dipping the substrate into a hydrofluoric acid thus removing silicon oxynitride.

Thereafter, a silicon nitride layer 12 having a thickness of 20 nm for protecting the surface strap portion is deposited by a chemical vapour deposition process in the trenches. By anisotropically plasma etching using  $\text{CHF}_3$ , the bottom portion of the silicon nitride layer as well as the silicon nitride layer on top of the boron silicate glass layer is removed.

Then, the upper capacitor electrode material 15 is further recessed by 1  $\mu\text{m}$  so as to define the collar region. To this end, again, an isotropic plasma etching step with  $\text{SF}_6$  is performed.

Again, the dielectric layer 7 is removed from the surface of the exposed trench wall, for example by a deglassing step which is performed by shortly dipping the substrate into a hydrofluoric acid thus removing silicon oxynitride (see Figure 10).

Then, the process of the present invention for producing the isolation collar 9 will be performed. The isolation collar is

provided for suppressing the parasitic transistor which otherwise would be formed in the upper trench region of a trench capacitor.

5 Accordingly, the step of roughening the surface of the exposed silicon portion is performed by etching in a stain etch, for example of  $\text{H}_2\text{SO}_4:\text{HF}:\text{HNO}_3 = 7:1:0.01$ , for a time sufficient so as to generate micropores extending in a depth of approximately 20 nm in the surface area.

10

Thereafter, a thermal oxidation step is performed. To this end, the wafer is placed in an oxidation furnace at  $1050^\circ\text{C}$  in an atmosphere of for example pure oxygen or water so as to form a silicon dioxide layer having a thickness of 25 nm.

15

More specifically, the porous surface portion is completely oxidized and, in addition, further 5 nm of the non-porous monocrystalline silicon material beneath the porous surface portion are oxidized. The process parameters are chosen in accordance with those usually employed. Since the upper part of the trench has been covered by a silicon nitride layer, the oxide layer will only be generated in the lower portion of the trench.

20

According to the present invention, the trenches having an oval diameter are covered by a uniform silicon dioxide layer having a homogenous thickness which is due to the roughening step performed.

25

Thereafter, the  $\text{SiO}_2$  layer on the bottom portion of the trenches is removed by anisotropically etching using  $\text{C}_4\text{F}_8$  as an etching gas. Optionally, a silicon nitride liner is deposited for protecting the collar region during the following process steps (see Figure 11).

30

Thereafter, the commonly used process for forming a DRAM cell is continued by connecting the upper capacitor electrode with the source/drain portions of an access transistor.

35

Accordingly, first, the trench portion is filled with polysilicon which is in situ doped. Then, the polysilicon trench fill is etched up to approximately 200 nm beneath the main surface 2. Thereafter, the trench walls are exposed for forming a buried strap. Accordingly, the protecting layers covering the trench wall are removed. In particular, the silicon nitride layer 12 is removed, for example, by etching in hot phosphoric acid.

After a sacrificial oxidation for forming a scattering oxide (not shown), an implantation step will be performed so as to create a  $n^+$ -doped region 14 in the side wall of each trench 5 in the main surface 2 portion.

As is shown in Figure 6, the space above the poly silicon fill in each of the trenches 5 will be filled by depositing in situ doped polysilicon and etching back the polysilicon with  $SF_6$  so as to form a polysilicon fill 11. The polysilicon fill 11 acts as a buried strap connecting the top capacitor electrode 8 and the  $n^+$ -doped region 14.

In a following step, isolation portions 13 for providing shallow trench isolation surrounding and defining the active areas are formed. To this end, a mask which defines the active areas is formed. By non-selectively plasma etching of silicon, silicon dioxide and polysilicon using  $CHF_3/N_2/NF_3$  with an etching time which is adjusted so as to etch 200 nm polysilicon, by removing the photoresist mask used therefor with  $O_2/N_2$ , by wet chemical etching of 3 nm dielectric layer, by oxidation and depositing a  $Si_3N_4$  layer having a thickness of 5 nm and by depositing a  $SiO_2$  layer having a thickness of 250 nm by a TEOS process and subsequent chemical mechanical polishing the isolation portions 13 are finished. The  $Si_3N_4$  layer 4 will be removed by etching in hot phosphoric acid and the  $SiO_2$  layer 3 will be removed by etching in diluted hydrofluoric acid.

Next, by performing a sacrificial oxidation a scattering oxide will be formed. Photolithographically generated masks and implantations will be used for forming n-doped wells, p-doped wells and for performing implantations for setting the threshold voltages in the peripheral portion and the access transistors of the cell array. Moreover, an implantation with high energetic ions will be performed for doping the substrate portion which is remote from the main surface 2. Thereafter, a  $n^+$ -doped region will be formed by a so-called buried-well implant for connecting neighbouring bottom electrodes 6 with each other.

In the following, the transistor will be completed by defining the gate oxide as well as the gate electrode 16, corresponding wirings and the source and drain electrode 15, respectively, using commonly used process steps.

Thereafter, the memory cell array will be finished in a commonly used manner by forming further metalization layers.

THIS PAGE BLANK (USPTO)

## Claims

1. A method of forming a silicon dioxide layer (9) comprising the steps of
  - 5 - providing a semiconductor substrate (1) having at least one silicon surface region having a curved surface,
  - roughening the surface of said at least one silicon surface region so as to produce a layer of porous silicon, and
  - 10 - thermally oxidizing said at least one roughened curved silicon surface region.
2. The method of claim 1, wherein said step of roughening the surface of said at least one silicon surface region comprises the step of producing pores having a diameter of less than 20  
15 nm in said surface region.
3. The method of claim 1 or 2, wherein said step of roughening the surface of said at least one silicon surface region comprises the step of etching said surface region.  
20
4. The method of any of claims 1 to 3, further comprising the step of covering the surface regions which are not to be oxidized with a silicon nitride layer (12) before roughening the surface of said at least one silicon surface region.  
25
5. The method of any of claims 1 to 4, wherein said step of thermally oxidizing said at least one roughened silicon surface is performed until an oxide layer thickness larger than the thickness of said layer of porous silicon is produced.  
30
6. The method of any of claims 1 to 5, wherein the silicon surface region is composed of monocrystalline silicon or is composed of polycrystalline silicon.
- 35 7. A method of producing an isolation collar (9) of a storage trench capacitor forming part of a memory cell comprising the steps of

- providing a semiconductor substrate (1) having a trench (5) with a curved inner surface of silicon, said trench (5) extending vertically with respect to the substrate surface (2),
- covering the surface regions which are not to be oxidized with a silicon nitride layer (12),
- roughening the surface of said curved silicon surface region so as to produce a layer of porous silicon, and
- thermally oxidizing said roughened curved silicon surface region.

10

8. The method of claim 7, wherein said step of roughening the surface of said curved silicon surface region comprises the step of etching said surface region.

15

9. The method of claim 7 or 8, wherein said step of roughening the surface of said curved silicon surface region comprises the step of producing pores having a diameter of less than 20 nm in said surface region.

20

10. The method of any of claims 7 to 9, wherein said step of thermally oxidizing said at least one roughened curved silicon surface region is performed until a oxide layer thickness larger than the thickness of said layer of porous silicon is produced.

## Abstract

## A Method of Forming a Silicon Dioxide Layer

5 The present invention refers to a method of forming a silicon dioxide layer by thermally oxidizing at least one monocrystalline silicon surface region on a semiconductor substrate, said silicon surface region having a curved surface. The present invention is advantageously applicable for the formation  
10 of the collar region in the upper part of the trench of a DRAM (Dynamic Random Access Memory) cell.

The method comprises the steps of providing a semiconductor substrate (1) having at least one monocrystalline silicon  
15 surface region having a curved surface, roughening the surface of said at least one monocrystalline silicon surface region so as to produce a layer of porous silicon, and thermally oxidizing (9) said at least one roughened monocrystalline silicon surface.
